Summary

Background Treatment of venous thromboembolism in children is based on data obtained in adults with little direct documentation of its efficacy and safety in children. The aim of our study was to compare the efficacy and safety of rivaroxaban versus standard anticoagulants in children with venous thromboembolism.

Methods In a multicentre, parallel-group, open-label, randomised study, children (aged 0–17 years) attending 107 paediatric hospitals in 28 countries with documented acute venous thromboembolism who had started heparinisation were assigned (2:1) to bodyweight-adjusted rivaroxaban (tablets or suspension) in a 20-mg equivalent dose or standard anticoagulants (heparin or switched to vitamin K antagonist). Randomisation was stratified by age and venous thromboembolism site. The main treatment period was 3 months (1 month in children <2 years of age with catheter-related venous thromboembolism). The primary efficacy outcome, symptomatic recurrent venous thromboembolism (assessed by intention-to-treat), and the principal safety outcome, major or clinically relevant non-major bleeding (assessed in participants who received ≥ 1 dose), were centrally assessed by investigators who were unaware of treatment assignment. Repeat imaging was obtained at the end of the main treatment period and compared with baseline imaging tests. This trial is registered with ClinicalTrials.gov, number NCT02234843 and has been completed.

Findings From Nov 14, 2014, to Sept 28, 2018, 500 (96%) of the 520 children screened for eligibility were enrolled. After a median follow-up of 91 days (IQR 87–95) in children who had a study treatment period of 3 months (n=463) and 31 days (IQR 29–35) in children who had a study treatment period of 1 month (n=37), symptomatic recurrent venous thromboembolism occurred in four (1%) of 335 children receiving rivaroxaban and five (3%) of 165 receiving standard anticoagulants (hazard ratio [HR] 0·40, 95% CI 0·11–1·41). Repeat imaging showed an improved effect of rivaroxaban on thrombotic burden as compared with standard anticoagulants (p=0·012). Major or clinically relevant non-major bleeding in participants who received ≥ 1 dose occurred in ten (3%) of 329 children (all non-major) receiving rivaroxaban and in three (2%) of 162 children (two major and one non-major) receiving standard anticoagulants (HR 1·58, 95% CI 0·51–6·27). Absolute and relative efficacy and safety estimates of rivaroxaban versus standard anticoagulation estimates were similar to those in rivaroxaban studies in adults. There were no treatment-related deaths.

Interpretation In children with acute venous thromboembolism, treatment with rivaroxaban resulted in a similarly low recurrence risk and reduced thrombotic burden without increased bleeding, as compared with standard anticoagulants.

Introduction

As a result of improved treatment and survival of children with life-threatening or chronic medical conditions and increased awareness among paediatricians, venous thromboembolism is being identified more often in childhood.^{1,2} The incidence of venous thromboembolism in children has been estimated at 0·01–0·05 per 1000 children per year,^{3–5} which is 20–100 times lower

than in adults.⁶ Children with venous thromboembolism constitute a challenge to paediatricians because, with only a single small randomised trial available,⁷ there is a paucity of data about the effectiveness and harms of anticoagulants in this group.⁸ Furthermore, the pathophysiology of thrombosis, its anatomical distribution, and pharmacological responses to anticoagulants differ between children and adults.^{1,8}

Research in context

Evidence before this study

Venous thromboembolism in children is predominantly seen in children with severe underlying medical or surgical problems. Guidelines for treatment of paediatric venous thromboembolism rely on low level paediatric evidence or are extrapolated from adult evidence. We searched PubMed for the period Jan 1, 1990, to Jan 1, 2019, using the terms "anticoagulants", "heparin", "vitamin K antagonist", "DOAC", "children", "paediatric", "treatment", "venous thromboembolism", and "randomised study". The single randomised trial which we identified was done in children with venous thromboembolism almost 20 years ago and was prematurely stopped after inclusion of only 76 children owing to slow enrolment. The trial compared intravenous unfractionated heparin followed by warfarin with subcutaneous administrations of the low molecular weight heparin reviparin followed by warfarin. Recurrent thromboembolism occurred in four (10%) of 40 children and major bleeding occurred in five (13%) of 40 children treated with unfractionated heparin and warfarin, compared with two (6%) of 36 and two (6%) of 36 children treated with reviparin and warfarin. Treatment of venous thrombosis in children is further limited by the absence of paediatric anticoagulant formulations, and the need for parenteral administration and for regular laboratory monitoring.

Fixed-dose treatment with the direct oral anticoagulant rivaroxaban is efficacious and safe for treatment of venous thromboembolism in adults. In the EINSTEIN-Jr phase 1 and 2 studies, bodyweight-adjusted rivaroxaban dose regimens with

tablets or a newly developed oral suspension have been established for children aged between birth and 18 years matching the exposure range of young adults treated with rivaroxaban 20 mg once daily.

Added value of this study

The EINSTEIN-Jr phase 3 study is the first completed trial of a direct oral anticoagulant in children and the largest trial of anticoagulant treatment ever done in children. The results show that treatment of children with venous thromboembolism with bodyweight-adjusted rivaroxaban tablets or suspension resulted in a similarly low recurrence risk and reduced thrombotic burden without increased bleeding compared with standard anticoagulants.

Implications of all the available evidence

Study outcomes and relative efficacy and safety of rivaroxaban versus standard anticoagulants in children were similar to those observed in adult studies on rivaroxaban treatment. Given this similarity of clinical course of venous thromboembolism, and relative treatment effects, the results of the EINSTEIN-Jr studies can be interpreted in the context of the body of evidence from adults, which overall provides sufficient evidence to inform practical use of rivaroxaban in children. The availability of the rivaroxaban suspension formulation will obviate the need for long-term treatment of children with parenteral anticoagulants.

Fixed-dose rivaroxaban is effective for treatment of venous thromboembolism in adults and is associated with a lower risk of major bleeding as compared with the traditional combination of heparin followed by a vitamin K antagonist.^{9–11} In collaboration with the European and US regulatory agencies, a strategy was developed to evaluate rivaroxaban for treatment of venous thromboembolism in children.^{12,13} In the EINSTEIN-Jr phase 1 and 2 studies,^{14–18} bodyweight-adjusted rivaroxaban dose regimens were established for children aged between birth to 17 years that matched the exposure range in adults younger than 45 years treated with rivaroxaban 20 mg once-daily.¹⁹

Anticoagulants given to young children are mostly parenterally administered,⁸ and are limited to dosage forms designed for adults that often need pharmaceutical manipulation to achieve the required paediatric dose.^{7,20} However, manipulations might affect the stability and bioavailability of these drugs, and are prone to dosing errors, thereby potentially jeopardising safety and efficacy.²⁰ To avoid these manipulations, as well as parenteral administration of anticoagulants, a rivaroxaban oral suspension was developed, which has similar pharmacokinetic properties to the tablet formulation.^{17,18} This suspension will enable precise dosing and easier administration, especially in young children.

We aimed to compare the efficacy and safety of bodyweight-adjusted paediatric rivaroxaban dose regimens with those of standard anticoagulants in children with acute venous thromboembolism who had completed at least 5 days of initial heparinisation.

Methods

Study design and participants

A randomised, open-label, phase 3 study was done comparing the efficacy and safety of rivaroxaban with those of standard anticoagulants for treatment of venous thromboembolism. The main study treatment period was 3 months, with the exception of children younger than 2 years who had catheter-related venous thromboembolism, for whom it was 1 month.²¹

Eligible children aged 0–17 years were recruited from 107 paediatric hospitals in 28 countries. The trial design has been published previously.²¹ The trial was done to meet the objectives outlined in both the European Medicines Agency Paediatric Investigational Plan,¹² and the Food and Drug Administration (FDA) Paediatric Research Equity Act Post-Marketing Requirements,¹³ with the study window set at 4 years of age. The protocol²² was approved by the institutional review board at each participating centre. Written permission from a parent or guardian and, when

appropriate, child assent, were obtained. An independent data monitoring committee periodically reviewed the study outcomes (appendix p 6). An independent adjudication committee, whose members were unaware of study group assignment, evaluated the initial diagnosis, all suspected outcomes, and repeat thrombosis imaging tests.

Children aged between birth to 17 years were potentially eligible if they had objectively confirmed venous thromboembolism for which heparin treatment was initiated. Children younger than 0.5 years were required to have a gestational age at birth of at least 37 weeks, a bodyweight above 2600 g, and to have had oral feeding for at least 10 days. Children were ineligible if they had active bleeding or were at a high risk of bleeding contraindicating anticoagulant therapy, had a platelet count of less than 50×10^9 cells per L, hepatic disease associated with a coagulopathy, severe renal impairment, or a life expectancy less than 3 months. The full list of eligibility criteria is provided in the appendix (p 8). The individual risk factor profile for venous thromboembolism was centrally classified as unprovoked, or provoked by a permanent or transient risk factor, or both.²²

Children commenced enrolment once the preceding phase 2 study had identified a rivaroxaban regimen for their bodyweight that matched the exposure in young adults treated with 20 mg rivaroxaban once-daily. The phase 2 study initially evaluated children aged 12–17 years followed by children aged 6–11 years, 2–5 years, and younger than 2 years.¹⁸ Consequently, inclusion in the current study occurred in the same order.

Randomisation and masking

Using an interactive online response system and permuted blocks of three, we randomly assigned children in a 2:1 ratio to receive open-label rivaroxaban or standard anticoagulants. Randomisation was stratified according to the age groups and site of venous thromboembolism (ie, cerebral vein or sinus thrombosis, or thrombosis of the caval, renal, portal, or jugular vein), and catheter-related venous thrombosis, and thrombosis of the lower or upper extremity (including subclavian and axillary vein), lungs, right heart, in the absence of a venous catheter. This trial was open-label, and investigators and patients and their families were aware of treatment assignment.

Procedures

Following completion of 5–9 days of anticoagulation with unfractionated heparin, low molecular weight heparin, or fondaparinux, children were randomised to standard anticoagulants or rivaroxaban. Children allocated to rivaroxaban received a bodyweight-adjusted 20 mg-equivalent dose, given once-daily (for bodyweights of ≥ 30 kg), twice-daily (for bodyweights of 12– <30 kg), or thrice-daily for bodyweights of, <12 kg) (appendix p 9). Rivaroxaban was administered as immediate release film-coated tablets available in strengths of 5, 10, 15, or 20 mg, or as suspension. The suspension was provided as

granules in a bottle that had to be filled with water to a concentration of 1 mg/mL and was administered by means of a standardised dosing device. Initially, rivaroxaban was administered as tablets, but once recruitment of children younger than 6 years of age was allowed, all newly randomised children received the suspension. Rivaroxaban was administered with an age-appropriate serving of fluid given with or shortly after a meal.

Children in the standard anticoagulants group continued with heparin treatment or switched to a vitamin K antagonist,²¹ at the discretion of the treating physician. Standard anticoagulation was given at therapeutic doses, according to international guidelines.^{8,21}

At monthly follow-up visits, a structured questionnaire was used to elicit signs and symptoms of study outcomes. At the end of the main treatment period, repeat thrombosis imaging was done, provided no additional ionising radiation or general anaesthesia was required. Patients and their guardians were instructed to report to the study centre if symptoms suggestive of recurrent venous thromboembolism or bleeding developed. Objective testing for confirmation was required for children with suspected outcome events.

Outcomes

The primary efficacy outcome was symptomatic recurrent venous thromboembolism, assessed by the central independent adjudication committee. The principal safety outcome was the composite of overt major and clinically relevant non-major bleeding (appendix p 10).^{23,24} Repeat imaging tests were compared with baseline and results were classified as normalised, (ie, no residual thrombus observed), improved (ie, thrombus still present but partly recanalised or involving less venous segments), no relevant change (ie, not recanalised and similar in extent), or deteriorated (ie, new venous segment involved; appendix p 11).²¹ Secondary outcomes were the composite of recurrent venous thromboembolism and deterioration on repeat imaging, and the composite of recurrent venous thromboembolism and major bleeding (net clinical benefit). In a separate publication, the pharmacokinetic and pharmacodynamic analyses in children belonging to the rivaroxaban group will be reported in detail.

Statistical analysis

A properly powered non-inferiority study was not feasible owing to the low incidence of venous thromboembolism in children and lack of well-documented information on recurrence and treatment effect with standard anticoagulants in children. Hence, there was no formal a priori sample size calculation.

Efficacy analyses included all randomised children, whereas safety analyses included those who had received at least one dose of study medication. Efficacy outcomes were considered during the main treatment period, whereas safety outcomes were considered for the main treatment period during the time from administration of

Table 1: Baseline characteristics

first dose of study drug to 2 days after administration of last dose. Efficacy and safety outcomes were analysed by means of a Cox proportional hazards model, stratified according to index event (ie, cerebral vein or sinus thrombosis, catheter-related venous thromboembolism, and non-catheter-related venous thromboembolism). Absolute differences in risk with 95% CIs were calculated. Kaplan-Meier curves were constructed to show the distribution of events over time. For the comparison of the ordered categories of change in thrombotic burden, the van Elteren test was used.²⁵ Results are presented descriptively and are compared with the historical 3-month efficacy and safety results of a programme which evaluated rivaroxaban versus standard anticoagulation in 8282 adult patients with acute venous thromboembolism.⁹⁻¹¹ Since young children might differ considerably from older children regarding demographics, clinical characteristics, risk factor profiles and treatment duration, we report these results for each age category separately without providing statistical analyses.

This trial is registered with ClinicalTrials.gov, number NCT02234843.

Role of the funding source

The funders contributed to study design, data collection, data analysis, data interpretation, writing of the report, and had the opportunity to review and comment on the manuscript before publication. Data were collected by the authors and their research teams. All authors had access to all study data and the first author had responsibility for the final version of the manuscript that was submitted.

Results

From Nov 14, 2014, to Sept 28, 2018, 500 (96%) of 520 children from 107 paediatric hospitals in 28 countries (ie, Australia, Israel, Japan, and China, and countries in Europe, South America, and North America) passed the screen of eligibility criteria and were randomised (appendix pp 3–5). Nine (2%) children did not take any study medication. One child in the standard anticoagulation group was lost to follow-up. Patient characteristics are in table 1. 117 (23%) had cerebral vein or sinus thrombosis (none catheter-related), 127 children (25%) had catheter-related venous thromboembolism, and 256 (51%) children had other, non-catheter-related venous thromboembolism (figure). Of the 127 children with catheter-related venous thromboembolism, 37 (29%) were younger than 2 years of age and had a main treatment period of 1 month. The most frequent sites of venous thromboembolism involved the lower extremities (165 children, 33%), cerebral veins or sinuses (117, 23%), lungs (80, 16%), upper extremities (58, 12%) and jugular vein (52, 10%). Venous thromboembolism was unprovoked in 56 children (11%) and provoked by persistent risk factors (87 children [17%]) or transient risk factors (236 [47%]), or the combination of both (115 [23%];

table 2). In the standard anticoagulation group, 106 children (64%) received parenteral anticoagulation with heparins only.

After a median follow-up of 91 days (IQR 87–95) in children who had a study treatment period of 3 months (n=463) and 31 days (IQR 29–35) in children who had a study treatment period of 1 month (n=37), symptomatic recurrent venous thromboembolism occurred in four (1%) of the 335 children in the rivaroxaban group and in five (3%) of the 165 children in the standard anticoagulation group (hazard ratio [HR] 0.40, 95% CI 0.11 to 1.41; table 3), and an absolute difference in risk of 1.8 percentage points (95% CI –0.6 to 6.0). Fatal venous thromboembolism did not occur.

Repeat imaging showed improved clot resolution with rivaroxaban as compared with standard anticoagulation (test for ordered categories, p=0.012; table 4). Complete resolution of the index thrombosis occurred in 128 children (38%) in the rivaroxaban group as compared with 43 children (26%) in the standard anticoagulation group (odds ratio [OR], adjusted for index event, 1.70 [95% CI 1.11–2.58]; p=0.012). Only one child in each treatment group had an asymptomatic deterioration (tables 3, 4). The demographics and clinical characteristics of children with study outcomes are shown in the appendix p 13.

*Active cancer is defined as presence of metastases, or recently (<6 months) diagnosed or treated. †Antiphospholipid syndrome (ie, lupus anticoagulant, anti-cardiolipin, or anti-β2-glycoprotein 1 antibodies, or both). ‡First degree (ie, parent or sibling). §In girls aged 12–17 years.

Table 2: Risk factor profiles

Clinically relevant bleeding was observed in ten (3%) of the 329 rivaroxaban recipients (all were non-major) and in three (2%) of the 162 standard anticoagulation recipients (two major and one non-major [HR 1.58, 95% CI 0.51 to 6.27]; table 3), an absolute difference in risk of 1.2 percentage points (95% CI -2.8 to 4.0). The major bleeding events presented as an intracranial and pulmonary bleeding. The composite of recurrent venous thromboembolism or major bleeding occurred in four (1%) of 335 children in the rivaroxaban group and seven (4%) of 165 children in the standard anticoagulation group (HR 0.30 [0.08 to 0.93]). The death of a single child in the rivaroxaban group was due to cancer progression. The most frequent adverse events during

the main study treatment period are listed in table 5, and a full list of adverse events is provided in appendix p 13–16.

In the rivaroxaban group, the upper margins of the 95% CIs of the incidences of recurrent venous thromboembolism, major bleeding, net clinical benefit, and mortality were comparable with results observed in adults (appendix p 17).^{9–11} Although the point estimate of the HR of the relative treatment effect of rivaroxaban versus standard anticoagulants was more favourable in children than in adults (ie, 0.40 vs 0.82), the upper margin of the 95% CI was slightly higher in children (ie, 1.41 vs 1.13). The Kaplan-Meier curves of recurrent venous thromboembolism and clinically relevant bleeding events in children who received

Table 4: Change in thrombotic burden on repeat imaging at the end of the main treatment period as compared with the index event

rivaroxaban were superimposable with those in adults (appendix p 18, 19).

Discussion

In children of all ages with various manifestations of venous thromboembolism, treatment with bodyweight-adjusted rivaroxaban, targeting the therapeutic exposure range of young adults, resulted in a low risk of recurrent venous thromboembolism and clinically relevant bleeding, similar to standard therapy. Moreover, treatment with rivaroxaban resulted in a greater reduction of thrombus mass as compared with standard therapy at repeat imaging. Study outcome rates and relative efficacy and safety of rivaroxaban were similar to findings from previous randomised trials evaluating rivaroxaban versus

standard anticoagulants in adults with venous thromboembolism.

The study could not be powered to independently show non-inferiority for efficacy of rivaroxaban in comparison to standard therapy in children; therefore, interpretation of the results relies in part on extrapolation of data obtained with rivaroxaban in adults. As a prerequisite for extrapolation according to FDA and European Medicines Agency paediatric guidelines,^{27,28} on the basis of comparison of the results of this paediatric study with those of large randomised studies in adults,^{9–11} we deduce a similar clinical course of venous thromboembolism, and similar relative treatment effects. The upper margin of the 95% CI of the HR for the main efficacy outcome of the comparison of

Data are n (%) of events (as defined by the *Medical Dictionary for Regulatory Activities*).²⁶ Data shown for all randomised patients who received at least one dose of treatment. All grade 4–5 events are shown, but grade 3 events are shown if they occurred in at least three (1%) children in the rivaroxaban group and at least two (1%) children in the standard anticoagulant group. Grade 1–2 events are only shown if there were grade 3 or worse events. Grade 1–2 events would also have been shown had they occurred in at least 5% of children. A single grade 5 event occurred (myxofibrosarcoma in the rivaroxaban group), which was not treatment related.

Table 5: Adverse events during the main study treatment period

rivaroxaban with standard anticoagulants was 1.41. In rivaroxaban treatment studies in adults,^{9–11} a non-inferiority margin of 1.75 was accepted because this margin preserves at least 75% of the established

treatment effect of standard anticoagulant therapy.²⁹ By use of this margin, or even the more stringent margin of 1.50 which was used in the venous thromboembolism treatment study with edoxaban,³⁰ bodyweight-adjusted

rivaroxaban treatment could be considered to be non-inferior to standard anticoagulants in children.

Certain features of the study require comment. First, we believe that the trial population is representative of the paediatric population with venous thromboembolism, since the broad range of manifestations of venous thromboembolism typically observed in paediatric practice were included and a short list of ineligibility criteria was applied. Approximately 90% of children had venous thromboembolism secondary to underlying disorders associated with hypercoagulable states such as cancer, trauma or surgery, major organ disease, thrombophilia and infection, while many had multiples of these risk factors. The proportion is distinctly different from the distribution of risk factors in adults in whom approximately half of the patients present with unprovoked venous thromboembolism,³¹ but is consistent with the known epidemiology of thrombosis in children.^{2-5,8,22} Second, the use of an open-label design is a potential weakness, but long-term administration of placebo injections and blood samples for sham laboratory monitoring in children randomised to rivaroxaban was considered to be neither ethical nor feasible. Hence, observer bias was limited by requiring objective tests when recurrent venous thromboembolism was suspected and by use of an independent adjudication committee unaware of study treatment assignment. Third, in adults, rivaroxaban is started without initial heparinisation and administered in a dose of 15 mg twice-daily for 3 weeks followed by 20 mg once-daily. Since many children with venous thromboembolism are referred from peripheral centres to more specialised centres and the process of obtaining informed consent in children is notoriously time consuming, most potentially eligible children had already received initial heparin treatment for several days. Therefore, we decided to deviate from the rivaroxaban regimen in adults and elected for an initial course of at least 5 days of heparinisation followed by rivaroxaban.

What are the clinical implications of this study's observations? We think physicians will have the option to treat children with bodyweight-adjusted oral rivaroxaban regimens, administered as tablet or suspension, without requiring regular laboratory monitoring and dose adjustments. Such anticoagulant regimens, validated in the paediatric venous thromboembolism population, obviate the need for manipulation of adult dosage forms, and substantially reduce the number of injections needed for standard anticoagulation treatment and associated blood sampling. Thus, the paediatric rivaroxaban regimens represent an advantageous alternative treatment for children with venous thromboembolism.

In summary, in children with acute venous thromboembolism, treatment with rivaroxaban in bodyweight-adjusted 20 mg-equivalent dose regimens resulted in a similar low risk of recurrent venous thromboembolism and improved clot resolution without increased bleeding, as compared with standard anticoagulation. Study

outcomes and relative efficacy and safety of rivaroxaban in children were similar to those observed in adults.
